Lecture 11: Belief propagation

Lecturer: Sasha Rush Scribes: Jiaoyang Huang

We've seen undirected graph model:

$$y_1 \longrightarrow y_2 \longrightarrow y_3 \longrightarrow \cdots \longrightarrow y_T$$

There are many algorithms to do inferences for undirected graph models

- Forward-backward
- Sum product algorithm
- Mean field
- Belief propagation
- Gibbs sampling
- MAP inference.

1 Time series

We denote the number of classes per node by V. The joint probability distributions of times series is given by

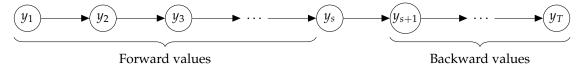

$$\begin{split} p(y_{1:T}) &= \exp\{\sum_t \theta_t^T(y_{t-1}, y_t) + \theta_t^o(y_t) - A(\theta)\} \\ &\propto \prod_t \psi_t(y_{t-1}, y_t) \psi_t(y_t), \end{split}$$

where $\psi_t(\cdot,\cdot)$ is a binary function, and $\psi_t(\cdot)$ is a unary function. The marginal distribution at y_s is given by

$$p(y_s = v) = \sum_{\substack{y'_{1:T} \\ y'_s = v}} \prod_t \psi(y'_{t-1}, y'_t) \psi(y'_t) / Z(\theta)$$

$$= \sum_{y'_T} \psi_T(y'_T) \sum_{y'_{T-1}} \psi_{T-1}(y'_{T-1}) \psi_T(y'_{T-1}, y'_T) \cdots \sum_{y'_2} \psi_2(y'_2) \psi_3(y'_2, y'_3) \sum_{y'_1} \psi_1(y'_1) \psi_2(y'_1, y'_2)$$

The sum can be performed in two directions, forwardly from y_1 , y_2 till y_{s-1} , and backwardly from y_T , y_{T-1} till y_{s+1} .

It takes $O(TV^2)$ steps to compute all margins with dynamic programming, i.e. $p(y_s = v)$ for all s, v.

2 Belief Propagation of Times Series

We can rewrite the above forward and backward computations in a fancier way. We define forward propagation:

$$\underbrace{\operatorname{bel}_{t}^{-}(y_{t})}_{\text{forward belief}} \propto \psi_{t}(y_{t}) \underbrace{m_{t-1 \to t}^{-}(y_{t})}_{\text{message}},$$

where the message is

$$m_{t-1 \to t}^-(y_t) = \sum_{y_{t-1}} \psi_t(y_{t-1}, y_t) \operatorname{bel}_{t-1}^-(y_{t-1}).$$

Similarly we define the backward propagation:

$$m_{t+1\to t}^+(y_t) = \sum_{y_{t+1}} \psi_{t+1}(y_t, y_{t+1}) \psi_{t+1}(y_{t+1}) m_{t+2\to t+1}^+(y_{t+1}).$$

Then the marginal probability is given by

$$p(y_t) = \text{bel}_t(y_t) \propto \underbrace{m_{t+1 \to t}^+(y_t)}_{\text{backward}} \underbrace{\text{bel}_t^-(y_t)}_{\text{forward}}.$$

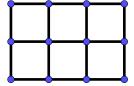

To compute all the marginal probability using the above algorithm, it takes $O(TV^2)$ time and O(TV) memory to store all the forward and backward values, i.e. $m_{t+1\to t}^+(y_t)$ and $\mathrm{bel}_t^-(y_t)$.

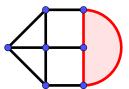

3 Belief Propagation of General Graphs

We have the belief propagation for time series, it is natural to ask undirected graph model defined by a general graph,

$$p(y_s = v) = \sum_{\substack{y'_{1:T} \\ y'_s = v}} \prod_{C} \psi_C(y'_C).$$

The above summation might be hard. For example, if C runs through cliques of size 5, the sum is over V^5 terms. Even if we start with a graph with maximum clique size \leq 2, the Ising model on 2d lattice, we will end up with larger cliques, i.e. cliques of size 3.

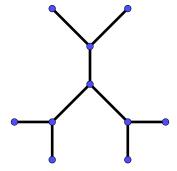

The minimum size of max clique induced -1 is the *treewidth* of a graph. Calculating the tree width of a graph is NP hard, and can be reduced to 3-SAT.

11.1 Belief Propagation on graphs with treewidth = 1

We derive the generalization of forward-backward sum product algorithm on trees.

For a tree graph, we can pick any vertex as a root, then for any vertex x_s the parent nodes set $pa(x_s)$ and children nodes set $ch(x_s)$ are well defined. The belief propagation consists of two parts: upward pass and downward pass. The upward pass is defined by

$$m_{s \to t}^-(x_t) = \sum_{x_s} \psi_{s,t}(x_s, x_t) \operatorname{bel}_s^-(x_s),$$

$$\operatorname{bel}_t^-(x_t) \propto \psi_t(x_t) \prod_{s \in ch(t)} m_{s \to t}^-(x_t).$$

The downward pass is defined by

$$bel_{s}(x_{s}) \propto bel_{s}^{-}(x_{s}) \prod_{t \in pa(s)} m_{t \to s}^{+}(x_{s}),$$

$$m_{t \to s}^{+}(x_{s}) = \sum_{x_{t}} \psi_{s,t}(x_{s}, x_{t}) \psi_{t}(x_{t}) \prod_{\substack{c \in ch(t), \\ c \neq s}} m_{c \to t}^{-}(x_{t}) \prod_{p \in pa(t)} m_{p \to t}^{+}(x_{t}).$$

To compute all the marginal probability using the above belief propagation, it takes $O(TV^2)$ time and O(TV) memory.

4 Some Remarks

1.
